1 Tree Recursion

Consider a function that requires more than one recursive call. A simple example is the recursive fibonacci function:

```python
def fib(n):
    if n == 0:
        return 0
    elif n == 1:
        return 1
    else:
        return fib(n - 1) + fib(n - 2)
```

This type of recursion is called tree recursion, because it makes more than one recursive call in its recursive case. If we draw out the recursive calls, we see the recursive calls in the shape of an upside-down tree:

```
fib(4)
  /   \
 /     \  
|       |
fib(3)  fib(2)
  /   \
 /     \  
|       |
fib(2)  fib(1)  fib(1)  fib(0)
```

We could, in theory, use loops to write the same procedure. However, problems that are naturally solved using tree recursive procedures are generally difficult to write iteratively. It is sometimes the case that a tree recursive problem also involves iteration: for example, you might use a while loop to add together multiple recursive calls.

As a general rule of thumb, whenever you need to try multiple possibilities at the same time, you should consider using tree recursion.

**How to diagram Tree Recursion**
Questions

1.1 You want to go up a flight of stairs that has \( n \) steps. You can either take 1 or 2 steps each time. How many different ways can you go up this flight of stairs? Write a function `count_stair_ways` that solves this problem. Assume \( n \) is positive.

Before we start, what’s the base case for this question? What is the simplest input?

When there is only 1 step, there is only one way to go up the stair. When there are two steps, we can go up in two ways: take a two-step, or take 2 one-steps.

What do `count_stair_ways(n - 1)` and `count_stair_ways(n - 2)` represent?

`count_stair_ways(n - 1)` represents the number of different ways to go up the last \( n - 1 \) stairs (this is the case where we take 1 step as our move).

`count_stair_ways(n - 2)` represents the number of different ways to go up the last \( n - 2 \) stairs (this is the case where we take 2 steps as our move).

Our base cases will take care of the remaining 1 or 2 steps.

Fill in the code for `count_stair_ways`:

```python
def count_stair_ways(n):
    if n == 1:
        return 1
    elif n == 2:
        return 2
    return count_stair_ways(n-1) + count_stair_ways(n-2)
```

Video Walkthrough (Diagramming Trees)
1.2 Consider a special version of the count_stairways problem, where instead of taking 1 or 2 steps, we are able to take up to and including \( k \) steps at a time.

Write a function \texttt{count\_k} that figures out the number of paths for this scenario. Assume \( n \) and \( k \) are positive.

\begin{verbatim}
def count_k(n, k):
    
    >>> count_k(3, 3)  # 3, 2 + 1, 1 + 2, 1 + 1 + 1
    4
    >>> count_k(4, 4)
    8
    >>> count_k(10, 3)
    274
    >>> count_k(300, 1)  # Only one step at a time
    1
    
    if n == 0:
        return 1
    elif n < 0:
        return 0
    else:
        total = 0
        i = 1
        while i <= k:
            total += count_k(n - i, k)
            i += 1
        return total

Video Walkthrough
\end{verbatim}
2 Lists

A sequence is an ordered collection of values. It has two fundamental properties: length and element selection. In this discussion, we’ll explore one of Python’s data types, the list, which implements this abstraction.

In Python, we can have lists of whatever values we want, be it numbers, strings, functions, or even other lists! Furthermore, the types of the list’s contents need not be the same. In other words, the list need not be homogenous.

Lists can be created using square braces. Their elements can be accessed (or indexed) with square braces. Lists are zero-indexed: to access the first element, we must index at 0; to access the $i$th element, we must index at $i - 1$.

We can also index with negative numbers. These begin indexing at the end of the list, so the index $-1$ is equivalent to the index $\text{len(list)} - 1$ and index $-2$ is the same as $\text{len(list)} - 2$.

Let’s try out some indexing:

```python
>>> fantasy_team = ['aaron rodgers', 'desean jackson']
>>> print(fantasy_team)
['aaron rodgers', 'desean jackson']
>>> fantasy_team[0]
'aaron rodgers'
>>> fantasy_team[len(fantasy_team) - 1]
'desean jackson'
>>> fantasy_team[-1]
'desean jackson'
```

List Slicing

If we want to access more than one element of a list at a time, we can use a slice. Slicing a sequence is very similar to indexing. We specify a starting index and an ending index, separated by a colon. Python creates a new list with the elements from the starting index up to (but not including) the ending index.

We can also specify a step size, which tells Python how to collect values for us. For example, if we set step size to 2, the returned list will include every other value, from the starting index until the ending index. A negative step size indicates that we are stepping backwards through a list when collecting values.
You can also choose not to specify any/all of the slice arguments. Python will perform some default behaviour if this is the case:

- If the step size is left out, the default step size is 1.
- If the start index is left out, the default start index is the beginning of the list.
- If the end index is left out, the default end index is the end of the list.
- If the step size is negative, the default start index becomes the end of the list, and the default end index becomes the beginning of the list.

Thus, \texttt{lst[:]} creates a list that is identical to \texttt{lst} (a copy of \texttt{lst}). \texttt{lst[::-1]} creates a list that has the same elements of \texttt{lst}, but reversed. Those rules still apply if more than just the step size is specified e.g. \texttt{lst[3:::-1]}.

```python
g>>> directors = ['jenkins', 'spielberg', 'bigelow', 'kubrick']
g>>> directors[:2]
['jenkins', 'spielberg']
g>>> directors[1:3]
['spielberg', 'bigelow']
g>>> directors[1:]
['spielberg', 'bigelow', 'kubrick']
g>>> directors[0:4:2]
['jenkins', 'bigelow']
g>>> directors[::-1]
['kubrick', 'bigelow', 'spielberg', 'jenkins']
```

**List Comprehensions**

A *list comprehension* is a compact way to create a list whose elements are the results of applying a fixed expression to elements in another sequence.

```
[<map exp> for <name> in <iter exp> if <filter exp>]
```

It might be helpful to note that we can rewrite a list comprehension as an equivalent for statement. See the example to the right.

Let's break down an example:

```
[x * x - 3 for x in [1, 2, 3, 4, 5] if x % 2 == 1]
```

In this list comprehension, we are creating a new list after performing a series of operations to our initial sequence \([1, 2, 3, 4, 5]\). We only keep the elements that satisfy the filter expression \(x \% 2 == 1\) \((1, 3, \text{and } 5)\). For each retained element, we apply the map expression \(x^2 - 3\) before adding it to the new list that we are creating, resulting in the output \([-2, 6, 22]\).
Note: The if clause in a list comprehension is optional.

Questions

2.1 What would Python display?

```python
>>> a = [1, 5, 4, [2, 3], 3]
>>> print(a[0], a[-1])
1 3

>>> len(a)
5

>>> 2 in a
False

>>> 4 in a
True

>>> a[3][0]
2
```

Video walkthrough

2.2 Write a function that takes a list and returns a new list that keeps only the even-indexed elements of lst and multiplies them by their corresponding index.

```python
def even_weighted(lst):
    return [i * lst[i] for i in range(len(lst)) if i % 2 == 0]
```

Alternatively, we can take advantage of the step size for range to make sure we only consider even numbered indices:
return [i * lst[i] for i in range(0, len(lst), 2)]

The key point to note is that instead of iterating over each element in the list, we must instead iterate over the indices of the list. Otherwise, there’s no way to tell if we should keep a given element.

One way of solving these problems is to try and write your solution as a for loop first, and then transform it into a list comprehension. The for loop solution might look something like this:

```python
result = []
for i in range(len(lst)):
    if i % 2 == 0:
        result.append(i * lst[i])
return result
```

Video walkthrough
2.3 Write a function that takes in a list and returns the maximum product that can be formed using nonconsecutive elements of the list. The input list will contain only numbers greater than or equal to 1.

```python
def max_product(lst):
    """Return the maximum product that can be formed using lst without using any consecutive numbers
    >>> max_product([10,3,1,9,2]) # 10 * 9 
    90
    >>> max_product([5,10,5,10,5]) # 5 * 5 * 5 
    125
    >>> max_product([]) 
    1 
    """

    if lst == []: 
        return 1 
    elif len(lst) == 1: # Base case optional 
        return lst[0] 
    else: 
        return max(max_product(lst[1:]), lst[0]*max_product(lst[2:]))
```

At each step, we choose if we want to include the current number in our product or not:

- If we include the current number, we cannot use the adjacent number.
- If we don’t use the current number, we try the adjacent number (and obviously ignore the current number).

The recursive calls represent these two alternate realities. Finally, we pick the one that gives us the largest product.
